THE LARGE RADIO GALAXY CENTAURUS A<br>
7.1 INTRODUCTION<br>
The nearby galaxy Centaurus A (NGC5128) has always been<br>
an object of extensive optical, and radio studies. It is one<br>
of the five brightest galaxies in t the nearest galaxy having an active nucleus and associated with an extended double radio structure. Its distance has been recently re-estimated from the light curve of the supernova 1987g placing it at  $\sim$  3 Mpc (Frogel et al., 1987). The Elliptical (E2) image of this galaxy is bisected by a of the five brightest galaxies in the sky  $(m_v \sim 6)$ , and also<br>the nearest galaxy having an active nucleus and associated<br>with an extended double radio structure. Its distance has<br>been recently re-estimated from the light roughly along a position angle of  $126^\circ$  (Baade and Minkowski, with an extended double radio structure. Its distance has<br>
been recently re-estimated from the light curve of the<br>
supernova 1987g placing it at  $\sim$  3 Mpc (Frogel et al., 1987).<br>
The Elliptical (E2) image of this galaxy thickness  $\sim$  1 kpc and having an inclination of  $\sim$  73<sup>°</sup> to the plane of the sky (Graham, 1979; Dufour et al., 1979; Marcelin et al., 1982).

The association of Cen A with the powerful radio source was first established by Bolton et al. (1949). The radio 1954). It is known to be a disk of diameter  $\sim 15$  kpc,<br>thickness  $\sim 1$  kpc and having an inclination of  $\sim 73^{\circ}$  to the<br>plane of the sky (Graham, 1979; Dufour et al., 1979; Marcelin<br>et al., 1982).<br>The association of  $\sim$  540 kpc, for the distance D  $\sim$  3Mpc. The radio source shows several peaks in its structure, forming an overall 5- shaped morphology (Haynes et al., 1983; Burns et al., 1983). This S shaped morphology is maintained even at size scales 2 orders of magnitude smaller, in the  $\sim$  7' arc double source (Maltby et al., 1963; Schwartz et al., 1973; Christiansen et al.,

1977; Burns et al., 1983) which is embedded in the optical<br>image of the galaxy (Fig.7.1a and 7.1b). The origin of this,<br>remarkable S-shaped radio structure is investigated in this image of the galaxy (Fig.7.la and 7.1b). The origin of this, remarkable S-shaped radio structure is investigated in this Chapter.

Faint, optical ripples or shell-like structures are known to be commonly associated with elliptical galaxies Solution 1977; Burns et al., 1983) which is embedded in the optical<br>
image of the galaxy (Fig.7.1a and 7.1b). The origin of this,<br>
remarkable S-shaped radio structure is investigated in this<br>
Chapter.<br>
Faint, optical rippl image of the galaxy (Fig.7.1a and 7.1b). The origin of this,<br>remarkable S-shaped radio structure is investigated in this<br>Chapter.<br>Faint, optical ripples or shell-like structures are<br>known to be commonly associated with ell (Schweizer, 1980; Malin and Carter, 1983). Recently even spiral galaxies have been shown to possess such shell systems (Schweizer and Seitzer, 1988). Considering only ellipticals, showing peculiar features (like tails, filaments, dust<br>
lanes) as well as those which are otherwise normal<br>
(Schweizer, 1980; Malin and Carter, 1983). Recently even<br>
spiral galaxies have been shown to possess such shell s showing peculiar features (like tails, filaments, dust<br>lanes) as well as those which are otherwise normal<br>(Schweizer, 1980; Malin and Carter, 1983). Recently ever<br>spiral galaxies have been shown to possess such shell syst and theoretical attempts to understand the formation of the (Schweizer, 1980; Malin and Carter, 1983). Recently even<br>spiral galaxies have been shown to possess such shell systems<br>(Schweizer and Seitzer, 1988). Considering only ellipticals,<br>shells are known to occur in  $\sim 10$  of a galaxies (Quinn, 1984). There have been many observational<br>and theoretical attempts to understand the formation of the<br>shells (observational: Schweizer, 1980, 1983; Malin and<br>Carter, 1980, 1983; Carter et al., 1982; Malin (Schweizer and Seitzer, 1988). Considering only ellipticals,<br>shells are known to occur in  $\sim 10$ <sup>8</sup> of all bright elliptical<br>galaxies (Quinn, 1984). There have been many observational<br>and theoretical attempts to understa Theoretical: Fabian et al., 1980; Quinn, 1982, 1984; Huang and Stewart, 1985; Williams and Christiansen, 1985; Kundt and and theoretical attempts to understand the formation of the shells (observational: Schweizer, 1980, 1983; Malin and Carter, 1980, 1983; Carter et al., 1982; Malin et al., 1983; Pence, 1986; Fort et al., 1986; Schweizer and 1987).

Optical shells are sharply defined, arc-like features, not completely encircling the parent galaxy. They have been and Stewart, 1985; Williams and Christiansen, 1985; Kundt and<br>Krause, 1985; Dupraz and Combes, 1986; Umemura and Ikeuchi,<br>1987).<br>Optical shells are sharply defined, arc-like features,<br>not completely encircling the parent central galaxy, along the major axis, and as near as  $\sim$  1 kpc from the galactic nucleus. One of their most characteristic properties is the inter-leaved disposition about the parent galaxy, i.e., the next outer shell occurs on the opposite side of the galaxy. Even the most sensitive optical observations carried out so far have failed to detect any emission lines. Their colours are seen to be bluer than, or similar to, those of the parent galaxy. From these results, it is has been been inferred that the shells are entirely made of stars. From photometric observations, it is deduced that the shells contain upto  $\sim$  10% of the mass of elliptical galaxy side of the galaxy. Even the most sensitive optical observa-<br>tions carried out so far have failed to detect any emission<br>lines. Their colours are seen to be bluer than, or similar<br>to, those of the parent galaxy. From thes been found that the shells occur mostly in galaxies located in sparsely populated environments (Quinn, 1984).

Among all the models for the shell formation the galaxy merger hypothesis first suggestd by Schweizer (1980) and later studied by several authors seems to account for most of observed properties of shells. Basically, in this model, the stars in different sections of the captured disk galaxy revolve about the centre of the  $\sim10$  times more massive galaxy with different periods, because of their different energies. The inner-most sections have the shortest periods observed properties of shells. Basically, in this model, the<br>stars in different sections of the captured disk galaxy<br>revolve about the centre of the  $\sim 10$  times more massive<br>galaxy with different periods, because of the velocities at the extremes of their oscillation, they spend most of their time at these extremities. The main deficiency of this model concerns the fate of the large amount of gas associated with the captured galaxy, in case it is a spiral.

The competing models for the shell formation, all involve interaction between an outflow from the parent galaxy and

some external medium. Stars form, from the resulting density enhancements as they cool. These models are inadequate in 115<br>some external medium. Stars form, from the resulting density<br>enhancements as they cool. These models are inadequate in<br>accounting for the important shell properties like their<br>interleaved distribution, their incomplete interleaved distribution,their incomplete arc-like structure, and the same or somewhat bluer colours (of the stars in the shell) as those in the parent galaxy.

In the context of the model proposed in this chapter for explaining the S shaped radio structure of Cen A, two properties of the shells are important: their gas content and their rotation about the galactic nucleus. Neither of these properties has been ruled out by the merger scenario. So far only 2 shell velocities have been determined but it has not explaining the S shaped radio structure of Cen A, two<br>properties of the shells are important: their gas content and<br>their rotation about the galactic nucleus. Neither of these<br>properties has been ruled out by the merger sc radial or circular relative to the nucleus (NGC3923; Quinn, 1982; NGC1316: Bosma et al., 1985). rotation about the galactic nucleus. Neither of these<br>rties has been ruled out by the merger scenario. So far<br>2 shell velocities have been determined but it has not<br>possible to establish if the measured velocities are<br>1 or

collinear. They may or may not contain emission peaks in their lobes. The C-shaped sources, WATs, HTs and NATs are all radial or circular relative to the nucleus (NGC3923; Quinn,<br>1982; NGC1316: Bosma et al., 1985).<br>Typical double radio galaxies, are more or less<br>collinear. They may or may not contain emission peaks in<br>their lobes. The C-sh sources (eg. NGC315) too have been explained in terms of the continuous beam model. According to Henriksen et al. (1981), the twin jet would be refracted towards the galaxy minor axis cheir lobes. The C-shaped sources, WATs, HTs and NATs are all<br>
Eound in galaxy clusters. Like them, the S or Z shaped<br>
sources (eg. NGC315) too have been explained in terms of the<br>
continuous beam model. According to Henri original direction of ejection. The S-shaped structure could sources (eg. NGC315) too have been explained in terms of the<br>continuous beam model. According to Henriksen et al. (1981),<br>the twin jet would be refracted towards the galaxy minor axis<br>(the direction of maximum pressure gra itself (eg. for NGC326, Ekers et al., 1978). The model of sources (eg. NGC315) too have been explained in terms of the<br>continuous beam model. According to Henriksen et al. (1981),<br>the twin jet would be refracted towards the galaxy minor axis<br>(the direction of maximum pressure gra

116<br>structure in terms of an interaction of the jets with the<br>shell segments rotating about the parent galaxy. shell segments rotating about the parent galaxy.

In the particular case of Cen A the S-shaped structure is delineated by discrete emission peaks, so any suggested model must also explain their origin. Haynes et al. (1983) proposed multiple nuclear outbursts along a precessing ejection axis.

The discovery and detailed studies of radio jets, which is delineated by discrete emission peaks, so any suggested<br>model must also explain their origin. Haynes et al. radio photographs of Cen A. It further allows us to place<br>
lower limit to the gas density in the optical shells, besides<br>
yielding constraints on the physical parameters of the jet. lower limit to the gas density in the optical shells, besides yielding constraints on the physical parameters of the jet. The shell is inferred to contain gas at significant levels, though its signature (emission lines) has not been directly detected despite several 1000 sec. of integration.

#### **7.2 COMPARISON OF RADIO AND OPTICAL MAPS**

#### **Radio maps:**

For the present study we make use of 3 radio maps of Cen A. The first **is** the Parkes map made at 1.4 GHz by Cooper et al. (1965) with a coarse angular resolution of 14' arc (Fig.7.1a). The third radio map shown in Fig.7.2a, coversed and the source shown in the new Parkes map of the source shown in the new Parkes' map of the source shown in Fig.7.1a). The new Parkes' map of the source shown in Fig.7.lc has been made at 5 GHz with a 4' beam (Haynes et al., 1983). The third radio map shown in Fig.7.2a, covers only a small region, containing the inner double radio source and has been made by Schreier et al. (1981) using the VLA at 1.4 GHz with a resolution of 10" x 31" arc. From this map it can be seen that the extensions of the two inner lobes indicate an inversion symmetry about the central core, in the same clockwise sense as displayed by the outer radio peaks (Fig.7.1). The nuclear radio source **is** seen to be joined to the base of the northern inner lobe by a roughly collinear chain of radio/X-ray knots (Schreier et al., 1981; Fig.7.2; indicate an inversion symmetry about the central core, in the<br>same clockwise sense as displayed by the outer radio peaks<br>(Fig.7.1). The nuclear radio source is seen to be joined to<br>the base of the northern inner lobe by a can be seen that the extensions of the two inner lobes<br>indicate an inversion symmetry about the central core, in the<br>same clockwise sense as displayed by the outer radio peaks<br>(Fig.7.1). The nuclear radio source is seen to (Dufour and van den Bergh, 1978; Graham and Price, 1981) it is known that the northern jet is likely to be approaching

**Figlla—c.** Shown are three wide-field pictures of Cen A. all reduced to the same angular scale and aligned in declination. These are: a The Parkes lA **GHz** map showing the two giant radio lobes of Cen A, stretched over  $\sim 10^3$  (Cooper et al., 1965). The four northern radio peaks and their southern counterparts are marked as A, *B,* C and *D* (see text). Note the clockwise progression in the position angles of the successively outer pairs of radio peaks. The central peak marked as *(A N, A <sup>5</sup>) is* seen resolved into two peaks,  $A_K$  and  $A_S$ , in c. b A specially processed, high-contrast photograph covering a  $\sim 2^{\circ} \times 3^{\circ}$  field around Cen A, reproduced from Malin (1978). The inset in the upper right corner shows a normally processed photograph of Cen A, the scale being the same as that of the main photograph. c The 5 GHz Parkes map of Cen A, reproduced from Haynes et al. (1983), after appropriately contracting their published map in east-west direction and thereby compensating for the expansion of the right ascension scale relative to the declination scale, as present on their map. The 'plus' mark near the centre refers to the position of the stellar nucleus of the galaxy, as defined by Kunkel and Bradt (1971). The dotted curve running northeast from the nucleus represents the outer **parts** of the optical jet, as published by Graham and Price (1981) (see text). The dashes plotted in the region of the radio lobe  $B<sub>N</sub>$  indicate the orientation of magnetic field, as inferred from the linear polarization map made by Gardner and Whiteoak (1971) at 5 GHz. The dash-dotted curve is a schematic representation of the giant shell-type structure of radius  $\sim 1^\circ$ , seen on the optical photograph in b. surrounding the main body of Cen A. The designations to the various radio peaks are given in a

Fig7.2 a The 1.4 GHz VLA map of the inner double source in Cen A (Schreier et al., 1981), superposed on the sketch of the optical features discovered recently in Cen A by Malin et al. (1983)and reproduced here from their paper. The shaded areas show absorption regions while the crosses indicate the positions of bright reference stars using which we have drawn the position coordinates. Full arcs represent the sharpest structures, broken arcs those more blurred. b same as a except that the radio map has been substituted with a high resolution, soft X-ray map published by Schreier et al. (19811. The X-ray peak coincident with the shell segment 9 has been designated as "G" by these authors

Fig.7.2(c) The optically detected shell segment 9, described by Malin et al. (1983), is superposed on the VLA 5 GHz map of the inner double radio source of Centaurus A, made by Burns et al. (1983). Absolute position of the shell segment was determined using the bright reference stars in its field, plotted by Malin et al.

#### **The optical photographs**

For both the optical photographs that are used by us for the study, the dynamic range has been greatly enhanced by employing techniques of unsharp masking and photographic amplification (Malin, 1977). The first photograph shown in The optical photographs<br>
For both the optical photographs that are used by us for<br>
the study, the dynamic range has been greatly enhanced by<br>

In Fig.7.1, the four radio peaks  $B_N$ ,  $A_N$ ,  $A_S$  and  $B_S$  fall around Cen A (Fig.7.1b and Fig.7.2). As will be seen below,<br>this plausible assumption seems to lead to a consistent<br>explanation for the rather complex radio morphology observed<br>in this galaxy.<br>7.3 RESULTS AND DISCUSSION<br>I One could therefore imagine them to represent the inner  $(A_M, B_M)$ 7.3 RESULTS AND DISCUSSION<br>
In Fig.7.1, the four radio peaks  $B_N$ ,  $A_N$ ,  $A_S$  and  $B_S$  fall<br>
on a straight line passing through the nucleus of Cen A.<br>
One could therefore imagine them to represent the inner  $(A_N$ ,<br>  $A_S$ ) a past, the component  $B_S$  was believed to be unrelated to In Fig.7.1, the four radio peaks  $B_N$ ,  $A_N$ ,  $A_S$  and  $B_S$  fall<br>on a straight line passing through the nucleus of Cen A.<br>One could therefore imagine them to represent the inner  $(A_N$ ,<br> $A_S)$  and middle  $(B_N$ ,  $B_S)$  radio lob background elliptical galaxy (Cooper et al., 1965; also Haynes et al., 1983). From the recent 5 GHz Parkes map (Fig.7.lc) whose absolute positional accuracy is believed to One could therefore imagine them to represent the inner  $(A_N)$ ,<br>
A<sub>S</sub>) and middle  $(B_N$ ,  $B_S)$  radio lobe pairs. However in the<br>
past, the component  $B_S$  was believed to be unrelated to<br>
Cen A, and instead thought to be ass peak B<sub>S</sub> Haynes et al., 1983). From the recent 5 GHz Parkes map<br>
(Fig.7.1c) whose absolute positional accuracy is believed to<br>
be better than 30" arc we measured the position of this<br>
peak B<sub>S</sub> as: RA(1950)=13<sup>h</sup>18<sup>n</sup>12.2<sup>5</sup>  $\pm$  past, the component B<sub>S</sub> was believed to be unrelated to<br>Cen A, and instead thought to be associated with a 15-mag<br>packground elliptical galaxy (Cooper et al., 1965; also<br>Haynes et al., 1983). From the recent 5 GHz Parkes (Fig.7.1c) whose absolute positional accuracy is belie<br>be better than 30" arc we measured the position of<br>peak  $B_S$  as:  $RA(1950)=13^h18^h12.2^S \pm 1.5^S$  and Dec (19<br> $43^O28'15'' \pm 20''$ . A check with the SRC/ESO survey<br>revea displaced by 2'.1  $\pm$  0'.7 from the radio peak B<sub>S</sub> along be better than 30" arc we measured the position of<br>peak  $B_S$  as: RA(1950)=13<sup>h</sup>18<sup>h</sup>12.2<sup>5</sup>  $\pm$  1.5<sup>5</sup> and Dec (19<br>43<sup>0</sup>28'15"  $\pm$  20". A check with the SRC/ESO survey<br>reveals that the centre of the said 15-mag gal.<br>dis PA  $25^\circ$ . Thus although part of the emission from B<sub>S</sub> may be associated with the background elliptical it seems more

120<br>
natural to consider the peak  $B_S$  as the counter-part of  $B_N$ ,<br>
particularly in view of its good alignment with the peaks  $B_N$ ,<br>  $A_N$  and  $A_S$ , and also considering its extension towards the particularly in view of its good alignment with the peaks  $B_N$ , A N 120<br>
tural to consider the peak  $B_S$  as the counter-part of  $B_N$ ,<br>
rticularly in view of its good alignment with the peaks  $B_N$ ,<br>
and  $A_S$ , and also considering its extension towards the<br>
cleus (Fig.7.1c). We therefore in nucleus (Fig.7.1c). We therefore interpret the radio peak  $B_S$ as having formed due to the impact of the counter-jet into natural to consider the peak  $B_S$  as the counter-part of  $B_N$ ,<br>particularly in view of its good alignment with the peaks  $B_N$ ,<br> $A_N$  and  $A_S$ , and also considering its extension towards the<br>nucleus (Fig.7.1c). We therefore surrounding Cen A. (see Fig.7.lb and 7.1c). This view is substantiated by the good spatial coincidence between the radio component  $B_S$  and the relevant section of the optical An and  $A_S$ , and also considering its extension towards the<br>nucleus (Fig.7.1c). We therefore interpret the radio peak  $B_S$ <br>as having formed due to the impact of the counter-jet into<br>the south western section of the giant extension of B<sub>S</sub>, which could conceivably result from the ter<br>A.<br>Beg<br>S' jet<br>as sweeping of the jet fluid by the shell in clockwise rotation about the galaxy as mentioned above (Fig.7.lc).

A radio enhancement is similarly seen near the shell (Fig./.1) and furthermore by the eastward radio<br>extension of  $B_S$ , which could conceivably result from the<br>sweeping of the jet fluid by the shell in clockwise rotation<br>about the galaxy as mentioned above (Fig.7.1c). -41 $^{\circ}$ 40', and we pair this radio peak  $\texttt{C}_{_{\rm N}}$  with the peak  $\texttt{C}_{_{\rm S}}$  in sweeping of the jet fluid by the shell in clockwise rotation<br>about the galaxy as mentioned above (Fig.7.1c).<br>A radio enhancement is similarly seen near the<br>northern section of the giant optical shell close to Dec. =<br> $-41^$ clearly paired with the peak  $D_S$ . Although the deep optical about the galaxy as mentioned above (Fig.7.lc).<br>
A radio enhancement is similarly seen near the<br>
northern section of the giant optical shell close to Dec. =<br>  $-41^{\circ}40'$ , and we pair this radio peak  $C_N$  with the peak  $C$ cover the region of the radio peaks  $D_N$ ,  $D_S$  and  $C_S$ , we suggest -41<sup>o</sup>40', and we pair this radio peak C<sub>N</sub> with the peak C<sub>S</sub> in<br>the southern lobe (Fig.7.1). The outermost peak D<sub>N</sub> could be<br>clearly paired with the peak D<sub>S</sub>. Although the deep optical<br>photograph shown in Fig.7.1b is shells paired with the peak  $D_S$ . Although the deep optical<br>photograph shown in Fig.7.1b is not extensive enough to<br>cover the region of the radio peaks  $D_N$ ,  $D_S$  and  $C_S$ , we suggest<br>that these peaks too owe their existe a distance of  $\sim$  200 kpc from the nucleus) but still embedded photograph shown in Fig.7.1b is not extensive enough to<br>cover the region of the radio peaks  $D_N$ ,  $D_S$  and  $C_S$ , we suggest<br>that these peaks too owe their existence to the presence of<br>shells farther out from the nucleus ( optical shells have been seen to occur at distances of as that these peaks too owe their existence to the presence of<br>shells farther out from the nucleus (requiring them to be at<br>a distance of  $\sim 200$  kpc from the nucleus) but still embedded<br>within the giant radio lobes. It can Athanassoula and Bosma, 1985). This postulated scenario is substantiated by the interpretation given below for the formation of the inner double radio source. Presently, it can be noted that all the 4 pairs of radio peaks, as proposed in our scheme are reasonably well aligned with respect to the galactic nucleus their axes showing a systematic progression in position angle (Fig.7.1).

In Fig.7.2a we have superposed the contours of the inner radio double and the shell segments found embedded inside the main body of Cen A described earlier. The most remarkable by well aligned with respect to the<br>galactic nucleus their axes showing a systematic progression<br>in position angle (Fig.7.1).<br>In Fig.7.2a we have superposed the contours of the inner<br>radio double and the shell segments fou coincidence of the shell segment 9 with the point from where onwards the jet outflow is no longer straight but begins to deflect towards northwest, accompanied by an abrupt rise in brightness and flaring in the transverse direction. It appears therefore that at this point the jet flow has been interrupted by the rotating shell (see below). The outermost X-ray knot detected in the jet of Cen A, designated as knot "G" by Schreier et al. (1981), also coincides with the shell, strengthening the case for the proposed collision of the jet with the shell segment 9 (Fig.7.2b). The bending of the jet is even more clearly visible on the 5 GHz map reproduced in Fig.7.2c from Burns et al. (1983).

If under the gravitational influence of the central galaxy, this shell segment is also rotating in the clockwise with the shell segment 9 (Fig.7.2b). The bending of the jet<br>is even more clearly visible on the 5 GHz map reproduced in<br>Fig.7.2c from Burns et al. (1983).<br>If under the gravitational influence of the central<br>galaxy, this sh around the main body of Cen A, the northward bending of the

jet, soon after its being interrupted by the shell 9, might have resulted due to the transverse momentum imparted by the shell medium to the jet fluid. Also the eastward extension observed in the SW inner radio lobe  $A_{\rm g}$  may have arisen due to the counter-jet being interrupted by a possible southwestern counterpart of the shell 9, whose detection would be rendered have resulted due to the transverse momentum imparted by the<br>shell medium to the jet fluid. Also the eastward extension<br>observed in the SW inner radio lobe  $A_S$  may have arisen due to<br>the counter-jet being interrupted by (Fig.7.2). Below, we shall explore the condition under which the postulated encounter with the shell 9 could have deflected the jet. erpart of the shell 9, whose detection would be rendered<br>cult due to obscuration caused by the dust lane<br>7.2). Below, we shall explore the condition under which<br>postulated encounter with the shell 9 could have<br>cted the je

velocity would be V<sub>S</sub> = {GMg( $\theta$  )/R<sub>S</sub>}<sup>1/2</sup>  $\simeq$  413 km S<sup>-1</sup> at the observed separation  $\hat{\sigma} \sim 3'$  arc from the nucleus (which the postulated encounter with the shell 9 could have<br>deflected the jet.<br>For the shell segment 9, the Keplerian rotational<br>velocity would be  $V_S = (GMg(\theta^-)/R_S)^{1/2} \approx 413$  km  $S^{-1}$  at the<br>observed separation  $\theta \sim 3'$  arc fr a distnace D = 3Mpc for Cen.A) and taking the galaxy mass to et al., 1982). In the case when the galactic mass is a few times higher as inferred from the recent analysis by Hesser et al. (1984), a value for  $V^S_s \sim 645$  kmS<sup>-1</sup> would be more appropriate. For the width of the shell 9 no good estimate is available presently. But from inspection of the photograph published by Malin et al. (1983), we estimate that the shell width  $d_S$  is unlikely to be smaller than the width of the jet which is  $d_i = 2r_i \approx 34$ " arc at the position where the jet appears to encounter the shell segment. Thus  $(d_S/d_{\frac{1}{1}}) \geq 1$ . The above estimate of  $d_i$  given by Burns et al. (1983) refers to the main jet which as found by these authors, is surrounded

kinetic energy of the jet fluid of density  $\int_{j}^{3}$  is converted<br>into radio emission inside the NE-inner lobe with a net<br>efficiency  $\ell$ , then<br> $L_{r} = \pi r_{j}^{2} v_{j} \gamma_{j} (\gamma_{j} - 1) \rho_{j} c^{2} \epsilon (\frac{r_{j}}{r_{\text{lobe}}})^{2/3} \dots (7.1)$ <br>wh by a 2-3 times wider sheath of radio emission. The energy flux I<sub>j</sub> flowing through the jet is estimated as follows: if the energy flux  $L_j$  through the jet carried in the form of into radio emission inside the NE-inner lobe with a net efficiency  $\ell$  , then

$$
L_r = \pi r_j^2 V_j Y_j (Y_j - 1) P_j c^2 \epsilon (\frac{r_j}{r_{\text{lobe}}})^{2/3} \dots (7.1)
$$

where

 

L<sub>r</sub> = observed radio luminosity of the N<sub>E</sub> inner lobe

From the equation (7.1) and (7.2), we obtained

transverse pressure of the shell and the jet, given by,  
ratio of the momenta of the shell and the jet, given by,  

$$
\tan \phi = \frac{\rho_s v_s^2}{\gamma_j^2 \rho_j v_j^2} (\frac{d_s}{d_j})
$$
...(7.2)  
From the equation (7.1) and (7.2), we obtained  

$$
\tan \phi = \frac{\pi \epsilon d_j^2 \rho_s v_s^2 c^2}{4 L_r v_j} (\frac{\gamma_j - 1}{\gamma_j}) (\frac{d_s}{d_j}) (\frac{d_j}{d_{\text{lobe}}})^{2/3}
$$
...(7.3)

From this relation one can obtain a useful limit to the density of gas in the shell. The true angle of deflection of the jet plasma can be derived from the apparent angle of deflection  $\eta \sim 40^\circ$  (Fig.7.2c) using the following expression from Readhead et al. (1980). t<br>=<br>-

$$
\eta = \tan^{-1} (\frac{\sin \phi \sin \psi}{\sin \theta \cos \phi + \cos \theta \sin \phi \cos \psi})
$$
\n(7.4)

Here  $\psi$  is the angle between the plane containing the tangent at the origin of the jet and the line of sight, and the plane containing the longitudinal axis of the jet.  $\theta$  is the angle of inclination of the jet from the line of sight.

Because of the nearness of Cen A, detailed kinematic studies of the dustlane have been possible which yielded a measure of the orientation of its rotation axis with respect to the line of sight of  $73^{\circ}$  +  $3^{\circ}$  (Graham, 1979; Marcelin et al., 1982). From studies of radio galaxies with jets and having dust lane in their parent galaxies (Kotanyi and Ekers, 1979; Ekers and Simkin, 1983) it has been inferred that the inner radio jet in Cen A, is likely to be within  $\sim 20^{\circ}$  of the rotation axis of the dustlane. Thus the inclination angle of the jet from the line of sight, . is likely to be >  $53^{\circ}$  +  $3^{\circ}$ .

Now, the true angle of deflection  $\phi$  would be minimised for

$$
\psi = \tan^{-1} \left( \frac{-\cot \eta}{\cos \theta} \right)
$$

For,<br>defle For,  $\eta \sim 40^{\circ}$  and  $\theta \ge 50^{\circ}$ , from Eq.(7.4), the true angle of For,  $\eta \sim 40^{\circ}$  and  $\theta \ge 50^{\circ}$ , for deflection  $\phi$  is atleast  $\sim 30^{\circ}$ <br>From Eq.(7.3), therefore the various parameters deflection  $\phi$  is atleast  $\sim$  30<sup>°</sup>.

It may be mentioned here that recently in the<br>
numerical simulation studies of jet disruption caused by<br>
shocks (Norman et al., 1988), the morphology of the northern<br>
lobe of the inner double in Cen A w segment used in our explanation. However, the possibility of shocks (Norman et al., 1988), the morphology of the northern<br>lobe of the inner double in Cen A was reproduced via an<br>oblique shock at the end of the jet. In this picture, the<br>hypothetical oblique shock replaces the observe shocks remains to be demonstrated. Moreover the idea of the twin jets interacting with the rotating shell segments hypothetical oblique shock replaces the observed shell<br>segment used in our explanation. However, the possibility of<br>the observed optical emission (non synchrotron) in such<br>shocks remains to be demonstrated. Moreover the id double. s remains to be demonstrated. Moreover the idea of the<br>s remains to be demonstrated. Moreover the idea of the<br>jets interacting with the rotating shell segments<br>ally explains the S-shaped structure of the inner<br>e.<br>The post

shell  $\,$  segment 9 for the past  $\sim$   $10^7$  yr is consistent with the conspicuous lack of radio emission between the radio peak  $A_c$ 

and the next-peak- $B_N^{\phantom i}$  (Fig.7.la; 7.lc). The relativistic particles that had already advanced beyond the location into which the rotating shell segment subsequently moved in (and thus began to interrupt the jet flow) have, in the meanwhile, continued to advance further into the region of the radio peak  $B_N^{\phantom i}$  and possibly further out, thus creating an emission trough between  $A_N$  and  $B_N$ . The lack of radio emission just beyond  $A_{N}$  (the NE inner lobe) is seen clearly on the VLA map (Fig.7.2a). In Fig.7.lc, the dotted curve drawn near the central region marks the location of several optical emission features and dust patches observed out to about 25' arc from the nucleus (as described e.g., by Blanco et al., 1975; Graham and Price,  $1981$ ). Within  $\sim 4'$  arc NE of the nucleus, i.e., in the region where the jet is almost straight and discernible in radio and X-rays, the optical filaments appear to line up along the jet (Brodie et al., 1983; Dufour and van den Bergh, 1978), but subsequently their chain gradually bends clockwise, ending up in the region of the radio component  $B_N$  (Fig.7.lc; 7.la). It has been suggested by several authors that the formation of these filaments lying close to the trajectory of the jet has been triggered due to compression produced by the passage of the jet material in past (e.g.,Osmer, 1978; Graham, 1983; see also DeYoung,1981).

The gradual clockwise bending of the optical jet between the peaks  $A_N$  and  $B_N$ , as described above, could again be understood within the framework of the postulated clockwise rotation of the circumgalactic medium. But the rather abrupt

128<br>bending towards north, exhibited by the radio contours just<br>beyond the peak B<sub>N</sub> seems more difficult to comprehend<br>(Fig.7.1c; 7.1a). This is particularly so because the region 128<br>bending towards north, exhibited by the radio contours just<br>beyond the peak B<sub>N</sub> seems more difficult to comprehend<br>(Fig.7.1c; 7.1a). This is particularly so because the region<br>of the abrupt bend seems to be devoid of 128<br>
bending towards north, exhibited by the radio contours just<br>
beyond the peak  $B_N$  seems more difficult to comprehend<br>
(Fig.7.lc; 7.1a). This is particularly so because the region<br>
of the abrupt bend seems to be devoid of the abrupt bend seems to be devoid of any conspicuous, beyond the peak  $B_N$  seems more difficult to comprehend (Fig.7.1c; 7.1a). This is particularly so because the region of the abrupt bend seems to be devoid of any conspicuous, sharp optical feature like a shell segment (Fi bending towards north, exhibited by the radio contours just<br>beyond the peak  $B_N$  seems more difficult to comprehend<br>(Fig.7.lc; 7.la). This is particularly so because the region<br>of the abrupt bend seems to be devoid of any polarization properties of the region seem to give some clue about the origin of the abrupt bend in the jet flow near  $B_M$ . According to Gardner and Whiteoak (1971), the degree of linear polarization at 5 GHz is very high in this region, attaining a maximum of  $\sim$  70% but generally remaining above bolarization properties of the region seem to give some clue<br>about the origin of the abrupt bend in the jet flow near  $B_N$ .<br>According to Gardner and Whiteoak (1971), the degree of<br>linear polarization at 5 GHz is very high ordered magnetic field which they found to be aligned in PA  $\sim$  144 $^{\rm O}$   $\,$  near $\,$  the peak  $\rm B_N$ . The field would thus  $\,$  be  $\,$  roughly linear polarization at 5 GHz is very high in this region,<br>attaining a maximum of  $\sim 70$  but generally remaining above<br>50 over a sizable area around  $B_N$ . This implies a highly<br>ordered magnetic field which they found to b of  $B_N$ . Note that the jet momentum and energy density has by over a sizable area around  $B_N$ . This implies a highly<br>ordered magnetic field which they found to be aligned in PA<br> $\sim 144^\circ$  near the peak  $B_N$ . The field would thus be roughly<br>orthogonal to the direction of the jet f attaining a maximum of  $\sim$  /0% but generally remaining above<br>50% over a sizable area around  $B_N$ . This implies a highly<br>ordered magnetic field which they found to be aligned in PA<br> $\sim 144^{\circ}$  near the peak  $B_N$ . The fie 50% over<br>

Fig.7.lc, sizable area around  $B_N$ . This implies a highly<br>netic field which they found to be aligned in PA<br>the peak  $B_N$ . The field would thus be roughly<br>to the direction of the jet flow into the region<br>e that the jet momentum and determined by the (well ordered) magnetic field. As seen from Fig.7.lc, there is indeed a striking agreement between the radio continuum ridge and the magnetic field orientation, as given by Gardner and Whiteoak, for the region beyond the peak  $B_{N}$ . Indeed, an analogous process may be responsible for the radio spur seen extending eastward in the southern lobe of Cen A between declinations  $-44^\circ$  and  $-44^\circ$ .5 (Fig.7.1c). The linear polarization observations of this region, also carried out by Gardner and Whiteoak (1971), again indicate a very

high degree of polarization (generally between 30% to 50% at 5 GHz) and a highly ordered magnetic field oriented eastwest, i.e., parallel to the radio spur observed in this part (Fig.7.lc).

## **CONCLUSIONS**

A detailed comparison of the deep radio, optical and Xwest, i.e., parallel to the radio spur observed in this part<br>
(Fig.7.1c).<br> **CONCLUSIONS**<br>
A detailed comparison of the deep radio, optical and X-<br>
ray maps of the nearest double radio galaxy Centaurus A has<br>
provided evide provided evidence to show that both the jet and counter-jet west, i.e., parallel to the radio spur observed in this part<br>
(Fig.7.1c).<br> **CONCLUSIONS**<br>
A detailed comparison of the deep radio, optical and X-<br>
ray maps of the nearest double radio galaxy Centaurus A has<br>
provided evide impinging on optically visible shell segments located many kiloparsec away from the galactic nucleus. This circumstance clearly appears to be responsible for the formation of radio hotspots marked as  $A_N$  and  $B_S$  (see Fig.7.1c and Fig.7.2a). The clockwise extension of radio contours, as witnessed in both these and several other prominent radio peaks in this source (Fig.7.l and Fig.7.2), as well as their inversion symmetric configuration with respect to the nucleus can be understood if one postulates a general clockwise rotation field for all clockwise extension of radio contours, as witnessed in both<br>these and several other prominent radio peaks in this source<br>(Fig.7.1 and Fig.7.2), as well as their inversion symmetric<br>configuration with respect to the nucleus medium asociated with Cen A. This scenario could be an alternative to the hypothesis of a sustained anti-clockwise precession of the central engine, as proposed by some authors (e.g., Haynes et al., 1983). Our proposition gains support from the observed spatial coincidence between the bright radio and optical features revealed by the recent deep observations of Cen A. Further, in view of such spatial coincidence, it appears likely that the radio peaks often develop where the relativistic plasma, either inside the jet or within the lobes, happens to encounter complexes of thermal gas and stars. Thus, it may not be essential to invoke repetitive outbursts of nuclear activity in order to understand the multiplicity of radio peaks on the opposite develop where the relativistic plasma, either inside the jet<br>or within the lobes, happens to encounter complexes of<br>thermal gas and stars. Thus, it may not be essential to<br>invoke repetitive outbursts of nuclear activity in or within the lobes, happens to encounter complexes of<br>thermal gas and stars. Thus, it may not be essential to<br>invoke repetitive outbursts of nuclear activity in order to<br>understand the multiplicity of radio peaks on the o high-contrast photograph of Cen A similar to that reproduced in Fig.7.lb, but covering the entire area all the way to the outermost radio peaks in the lobes of Cen A.

The deflection of the jet due to encounter with the analysis of the situation would be possible by obtaining a<br>high-contrast photograph of Cen A similar to that reproduced<br>in Fig.7.1b, but covering the entire area all the way to the<br>outermost radio peaks in the lobes of Ce in Fig. 7.1b, but covering the entire area all the way to the<br>outermost radio peaks in the lobes of Cen A.<br>The deflection of the jet due to encounter with the<br>shell segment 9 and the resultant formation of the north-<br>east seems feasible for a gas density in the shell of  $\geq 3.10^{-28}$  gm  $cm^{-3}$ . If, as in the case of this radio lobe, the shell responsible for the formation of any given radio lobe can be shell segment 9 and the resultant formation of the north-<br>eastern inner radio lobe  $(A_N)$ , as proposed in our model,<br>seems feasible for a gas density in the shell of  $\geq 3.10^{-28}$  gm<br>cm<sup>-3</sup>. # **CONSTRAINTS ON SOME PHYSICAL PARAMETERS OF CLASSICAL DOUBLE RADIO SOURCES**

#### **8.1 INTRODUCTION**

CHAPTER VIII<br>
CONSTRAINTS ON SOME PHYSICAL PARAMETERS OF<br>
CLASSICAL DOUBLE RADIO SOURCES<br>
INTRODUCTION<br>
Radio galaxies with their classical double radio<br>
ology are best understood in terms of the continuous<br>
model (Blandfo morphology are best understood in terms of the continuous beam model (Blandford and Rees, 1974; Scheuer, 1974). In this model, basically there is a continuous supply of energy from the active nucleus of the parent galaxy to the outer regions, in the form of a pair of anti-parallel "jets" or "beams" of relativistic plasma and magnetic field. In the case of Radio galaxies with their classical double radio<br>norphology are best understood in terms of the continuous<br>beam model (Blandford and Rees, 1974; Scheuer, 1974). In this<br>model, basically there is a continuous supply of ener supersonic, which upon impinging on the external medium create shocks on either side of the 'contact discontinuity'. In the region after the reverse shock, the directed flow of the beam plasma gets disrupted and the velocities are significantly randomized. The ensuing substantial radiative losses in that region give rise to a radio "hotspot". Only a fraction of the kinetic power of the beam plasma is used up in producing relativistic plasma inside the hotspot and of that only a fraction is lost as radiation. While radiating away part of their energy inside the continuously advancing hotspot, the particles are subjected to the ram pressure of the external medium and, thus, stream in the direction of the nucleus, filling an extensive region called a "lobe" or "bridge". In this region the electrons with reduced energies

132<br>(due to adiabatic expansion losses) radiate in diluted<br>magnetic fields. magnetic fields.

Intrinsic parameters derived from the observations of these sources are essential for arriving at an understanding of the relevant physical processes. In this chapter we obtain some of the diabatic expansion losses) radiate in diluted<br>magnetic fields.<br>Intrinsic parameters derived from the observations of<br>these sources are essential for arriving at an understanding<br>of the relevant physical proces sample of 10-bright, powerful  $(\texttt{L}\,{\sim}10^{\textstyle 44}\textstyle\overset{\textstyle +}{\textstyle -}1\textstyle \textstyle \textstyle \text{e}^{-1})$  hotspots (Saripalli and Gopal-Krishna, 1985). This approach, also these sources are essential for arriving at an understanding<br>of the relevant physical processes. In this chapter we obtain<br>some of the intrinsic parameters using a representative<br>sample of 10 bright, powerful  $(L \sim 10^{44 \pm$ and dynamics of the jet-hotspot interaction. Such a study is some of the intrinsic parameters using a representative<br>sample of 10 bright, powerful  $(L \sim 10^{44} \text{H}^{-1} \text{erg s}^{-1})$  hotspots<br>(Saripalli and Gopal-Krishna, 1985). This approach, also<br>employed by Perley et al. (1984), is ba which possess hotspots near their extremities (Fanaroff and Riley, 1974). palli and Gopal-Krishna, 1985). This approach, also<br>yed by Perley et al. (1984), is based on the energetics<br>ynamics of the jet-hotspot interaction. Such a study is<br>lly possible only for powerful double radio sources<br>posses

intrinsic parameters of a radio source like its beam power, it is essential to know the level of efficiency with which the bulk kinetic energy of the beam gets converted into radio power. For example, a powerful radio source could be formed with intrinsically weak beams provided the conversion efficiency is high and vice versa. Giant radio galaxies are examples where although they appear to be relatively weak in their radio output (Saripalli et al., 1986), their beams are, very likely intrinsically powerful (Gopal-Krishna, Wiita and Saripalli, 1988; also see Chapter VI). The determination of this efficiency factor is difficult, as one must include all possible loss mechanisms like adaibatic expansion losses, inverse Compton losses, losses incurrerd due to entrainment

(De Young, 1986), - thermal plasma heating (Eilek, 1982) etc. Moreover, these are all model dependent (see Rawlings and Saunders, 1988). Even so, values of 1-30% have been estimated 13:<br>(De Young, 1986), thermal plasma heating (Eilek, 1982) etc<br>Moreover, these are all model dependent (see Rawlings and<br>Saunders, 1988). Even so, values of 1-30% have been estimated<br>for the conversion efficiency in the li 1984; Begelman, Blandford and Rees, 1984; Gopal-Krishna and Saripalli, 1984a; Gopal-Krishna, Wiita and Saripalli, 1988). bung, 1986), thermal plasma heating (Eilek, 1982) etc.<br>
ver, these are all model dependent (see Rawlings and<br>
ers, 1988). Even so, values of 1-30% have been estimated<br>
the conversion efficiency in the literature (Dreher,<br>

properties of 10 powerful sources, possessing bright, compact hotspots, to calculate the efficiency of conversion of beam power into synchrotron radio power from the hotspot, making some simple assumptions, which are spelled out in the next In this chapter we use the observed jet-hotspot<br>properties of 10 powerful sources, possessing bright, compact<br>hotspots, to calculate the efficiency of conversion of beam<br>power into synchrotron radio power from the hotspot, unity, the analysis yields rather stringent lower limits to the bulk velocity of the beam material (which cannot be measured directly).

From a variety of observational evidences, it is well established that the beams are relativistic on parsec scales (see, Bridle and Perley, 1984; Begelman, Blandford and Rees, 1984). However, on the kilo-parsec scales the situation is far from being clear (see review by Bridle, 1986). Support for relativistic velocities on kiloparsec scales comes from the observed one-sidedness of parsec and kilo-parsec jets occurring on the same side of the nucleus (Scheuer, 1987), and more recently, from the depolarization asymmetries in the lobes of classical double radio sources (Laing, 1988). for relativistic velocities on kiloparsec scales comes from<br>for relativistic velocities on kiloparsec scales comes from<br>the observed one-sidedness of parsec and kilo-parsec jets<br>occurring on the same side of the nucleus (S

As<br>shown by Jenkins and McEllin (1977), the fractional flux in<br>the hotspots [defined as C = (Flux density from assumptions namely, an equipartition of energy between the radiating particles and magnetic field and a spherical shape for the hotspots, to explain the C-L correlation. New interluminosity, L, of the source. In Section 8.2, we sketch a<br>scenario based on the beam model, and on the simple<br>assumptions namely, an equipartition of energy between the<br>radiating particles and magnetic field and a spheric properties are derived. It is found that hotspots powered by non-relativistic beams  $(V_h \leq 0.1c)$  can atmost ce. In Section 8.2, we sketch a<br>am model, and on the simple<br>ipartition of energy between the<br>netic field and a spherical shape<br>n the C-L correlation. New inter-<br>source luminosity and hotspot<br>is found that hotspots powered

luminosities of  $\sim 10^{44}$ <br>relativistic beams can a<br>distinct change in the mo erg s $^{-1}$ 135<br>
While those powered by<br>
uch higher luminosities. A<br>
p of the hotspots is found to relativistic beams can attain much higher luminosities. A distinct change in the morphology of the hotspots is found to occur for luminosities  $\geq 10^{46}$  erg s $^{-1}$  (Gopal-Krishna and Saripalli, 1984a). The slab-like geometry inferred for such powerful hotspots resembles the reported sub-arcsecond resolution maps of hotspots in some powerful radio sources (Dreher, 1981; Begelman, Blandford and Rees, 1984). Saripalli, 1984a). The slab-like geometry inferred for such<br>powerful hotspots resembles the reported sub-arcsecond<br>resolution maps of hotspots in some powerful radio sources<br>(Dreher, 1981; Begelman, Blandford and Rees, 19

#### **8.1.1 Constraints on the jet/hotspot parameters**

is radio luminous (L $\sim$ 10<sup>44</sup>  $\pm$  1 erg s<sup>-1</sup>) and compact, having a radius  $r_{\rm hs}$   $\leq$  1 kpc which is atleast 100 times smaller than the overall size of the associated radio source. The observed parameters of these representative, bright hotspots are listed in Table 8.1.1. Also listed are the flux density  $S_{\alpha}$  at some frequency  $\sqrt{2}$  and the ratio of the hotspot flux to that of the radio lobe associated with it. A Hubble constant of  $H_0$  $=$  75 kms $^{-1}$  Mpc $^{-1}$  and  $q^{\circ}$  = 0 have been used in this section.

Assumptions : The hotspots are assumed to be spherical and filled uniformly with relativistic electrons and magnetic field, radiating under the condition of minimum energy density (Burbidge, 1959). The radio spectrum of the hotspot is assumed to be straight between a turnover frequency  $\vartheta_+$ , due to synchrotron self-absorption, and an upper limiting frequency  $\delta_{\rm u}$  = 10 GHz (Scheuer, 1982).

The derived physical parameters of the hot spots and of the associated jets<sup>\*</sup>

The values given in the first and second row for each hot spot refer to  $\alpha = -0.6$  and  $-0.9$ , respectively. ( $\alpha$  is defined as:  $S_v \sim v^2$ ). These values of  $\alpha$  essentially cover the range relevant for hot spots (e.g., Miley, 1980; Bedford et al., 1981)

\_ gives for each hot spot the Lorentz factor v ein le down to 139<br>gives for each hot spot the Lorentz factor  $\gamma_{\rho}^{min}$  down to<br>which, at least, the energy spectrum of the relativistic<br>electrons should continue to rise. In terms of the spectral<br>turnover frequency  $\gamma_t$  (Table 8.1.2), it is expressed as:<br> $\gamma_{\rm e}^{\rm min} \sim 0.5[\nu_t(1+z)/\beta_{\rm hs}]^{1/2}$ <br>8.1.

#### **8.1.3 Discussion**

The limits to the various jet parameters, as derived  $y_e^{\text{min}} \sim 0.5 \left[ v_t(1+z)/B_{\text{hs}} \right]^{1/2}$ <br>
8.1.3 Discussion<br>
The limits to the various jet parameters, as derived<br>
above, within the framework of the beam model, are<br>
conservative estimates since they refer to the maximum<br> possible value of the jet radius (i.e.,  $r^{\phantom{\dagger}}_{\tt i}$  = $r^{\phantom{\dagger}}_{\tt h c}$ ). As seen from Table 8.1.2, the hot spots in our sample must radiate away The limits to the various jet parameters, as derived<br>above, within the framework of the beam model, are<br>conservative estimates since they refer to the maximum<br>possible value of the jet radius (i.e.,  $r_j=r_{hs}$ ). As seen fro efficiency of 2-25%. Clearly, these lower limits to  $\epsilon$  would conservative estimates since they refer to the maximum<br>possible value of the jet radius (i.e.,  $r_j=r_{hs}$ ). As seen from<br>Table 8.1.2, the hot spots in our sample must radiate away<br>the jet kinetic power supplied to them at a assumed condition of minimum total energy (Eq.8.4). But, from Table 8.1.2, the hot spots in our sample must radiate away<br>the jet kinetic power supplied to them at a minimum<br>efficiency of 2-25%. Clearly, these lower limits to  $\epsilon$  would<br>have to be relaxed, should the hot spots depart apply for such extended radio structures (Scott and Readhead, 1977; Marshall and Clark, 1981; Scherier et al., 1982; efficiency of 2-25%. Clearly, these lower limits to  $\epsilon$  would<br>have to be relaxed, should the hot spots depart from the<br>assumed condition of minimum total energy (Eq.8.4). But, from<br>the available evidence, this assumption bulk velocities  $(v_i^{min}$ nce, this assumption appears to broadly<br>
led radio structures (Scott and Readhead,<br>
clark, 1981; Scherier et al., 1982;<br>
bter VII). Secondly, the adopted upper<br>
3 yields a range c/7-c for the minimum<br>
in) for the beam flui the available evidence, this assumption appears to broadly<br>apply for such extended radio structures (Scott and Readhead,<br>1977; Marshall and Clark, 1981; Scherier et al., 1982;<br>Roland, 1982; (Chapter VII). Secondly, the ad 1977; Marshall and Clark, 1981; Scherier et al., 1982;<br>Roland, 1982; (Chapter VII). Secondly, the adopted upper<br>limit of  $\epsilon_{\text{max}} = 0.3$  yields a range c/7-c for the <u>minimum</u><br>bulk velocities (V<sub>J</sub><sup>min</sup>) for the beam flui the hot spots. But, as in the case of  $\epsilon$ , the derived lower limits to both  $V_{\dot{1}}$  and  $V_{\text{out}}$  are dependent on the assumption of minimum energy for the hot spots. On the other hand, they would not be violated on account of the other assumption made in the previous section, that the spectra of the hotspots remains straight only up to 10 GHz. The same applies to the parameters  $\rho_i^{\text{max}}, \dot{N}_j^{\text{max}},$  and  $\rho_{h_5}^{\text{max}},$  given in Table 8.1.2. It may i<br>'Y<br>' also be noted from Eq.(8.6), that the outflow velocity  $V_{\text{out}}$ . of relativistic plasma from the hot spots is expected to be higher for faster jets, attaining a maximum value of  $\sim 0.25c$ for an ultra-relativistic jet. The upper limit does not depend on the assumption of minimum energy condition [Eq.(8.6)]. Another parameter which is fairly insensitive to this assumption is  $\gamma_{\rho}^{\text{ min}}$  which represents the Lorentz factor below which the energy spectrum of relativistic electrons responsible for the radio output from the hot spot cuts off [from Eqs.(8.1) and (8.7);  $Y_{\text{e}}^{\text{min}} \propto B^{-2/5}$ ]. From Table 8.1.2, it is seen that the values of  $Y_{\rho}^{min}$  for all the 10 hot spots lie in a rather narrow range:  $\gamma_{\rho}^{min} = 250 + 50$ . It is interesting that Faraday rotation measurements have indicated a similar lower limit to the Lorentz factors of relativistic electrons present inside compact radio sources coincident with active galactic nuclei (Wardle, 1977).

# **8.2. CONSTRAINTS ON THE LUMINOSITY ATTAINED BY HOTSPOTS 8.2.1 Some General Constraints on the Hotspots**

The theory of synchrotron radiation tells us that the synchrotron luminosity L of a source increases not only with U, the total energy present in the form of relativistic electrons and magnetic field, but also with the pressure p due to them: [L  $\propto$  U.p $^{3/4}$ . Thus, for a given amount of beam

power being discharged into the hot spot, the nonthermal radiation from the hot spot would be maximum when the pressure of the synchrotron plasma inside the hot spot is at the highest possible value. Here, one could place two general constraints on hot spots. Firstly, in order to ensure the flow of the beam plasma into the hotspot, the internal pressure of the hot spot  $p_{hs}'$ , can at most be as high as the directed pressure of the beam plasma at the beam outlet,  $P_{bo}$ (we refer to this equilibrium configuration with  $p_{bo} = p_{hs}$  as 'maximally radiating' hot spot). The second constraint is that the radius of the hot spot  $r_{hs}$ , cannot be smaller than the radius of the beam outlet,  $r_{\rm bo}$ , around which the hot spot pressure of the hot spot p<br>directed pressure of the b<br>(we refer to this equilibr<br>'maximally radiating' ho<br>that the radius of the hot<br>the radius of the beam out<br>forms ( $\eta = r_{\text{hs}}/r_{\text{bo}} \geq 1$ ).<br>attainable radio luminosit attainable radio luminosity, we express the first constraint pertaining to a maximally radiating hot spot, in steady state, as e la<br>ius (  $\eta$ <br>ble ling<br>as:<br> $[\mathbf{p}_{\text{bo}}]$ <br>ere 1: C 1<br>2<br>2<br>2<br>bu 1). Thus, for estimating the maximum<br>osity, we express the first constraint<br>mally radiating hot spot, in steady<br> $\begin{bmatrix} 2 \\ b_0 \end{bmatrix} = [p_{hs} \sim u_{hs}^{min}/4\pi r_{hs}^3]$  ...(8.7)<br>bulk velocity of the beam plasma whose

$$
[p_{bo} \sim L_{hs} / \pi \epsilon \beta c r_{bo}^{2}] = [p_{hs} \sim U_{hs}^{min} / 4 \pi r_{hs}^{3}]
$$
 (8.7)

Here  $\beta$  c is the bulk velocity of the beam plasma whose kinetic power  $L_b = L_{hs}/\epsilon$  gets converted into radio luminosity  $L_{hs}$  of the hot spot with the net conversion efficiency  $\epsilon$  . U<sup>min</sup> is the total energy inside the hot spot in the form of magnetic field and relativistic electrons, computed for the usual equipartition condition defined by Burbidge (1959) (we shall ignore other possible forms of energy). If, now, one makes a reasonable assumption that the power radiated from the hot spot is mainly concentrated within the frequency range 100 MHz to  $10^4$  MHz (the results

are not very sensitive to an order-of-magnitude uncertainty in these figures) with a spectral index  $\alpha$  = +0.75 (defined  $\tilde{\mathcal{R}}$ are not very sensitive to an order-of-magnitude uncertainty<br>
in these figures) with a spectral index  $\alpha$  = +0.75 (defined<br>
as :  $S_y \alpha \overline{\delta}^{\alpha}$ ) one obtains from the synchrotron theory<br>
(Moffet, 1968). (Moffet, 1968). to an<br>a spe<br>btains<br> $\frac{L_{hs}}{reg/s}$ , 2 very sensitive to an order-of-magni<br>
e figures) with a spectral index  $\propto$ <br>  $S_y \propto \tilde{v}^{\infty}$  one obtains from the sy<br>
1968).<br>
U<sup>min</sup>  $\simeq 2.6.10^4$  ( $\frac{L_{\text{hs}}}{\text{erg/s}}$ )<sup>4/7</sup> ( $\frac{r_{\text{hs}}}{\text{cm}}$ )<sup>9/7</sup> erg.<br>
9 Eq.8.7 an

1968).  
\n
$$
U_{hs}^{\min} \approx 2.6.10^{4} \left( \frac{L_{hs}}{\text{erg/s}} \right)^{4/7} \left( \frac{r_{hs}}{\text{cm}} \right)^{9/7} \text{erg.}
$$
\n...(8.8)

# **8.2.2. Efficiency and Bulk Velocity of a Beam and the Radio Luminosity**

Among the 3 variables on the right side in Eq.8.10, both  $\beta$  and  $\beta$  must clearly be <1 and  $\eta$  must be > 1, as discussed earlier. In reality, the efficiency  $f$  is expected to be well below 100%. This reasonable expectation is also consistent with the observation that even in highly luminous double sources a small amount of radio emission does arise from lobes surrounding the hot spots (e.g., Swarup et al., 1984;

143<br>Barthel, 1983). Most probably such lobes are formed due to<br>relativistic electrons escaping out of the hot spots and<br>therefore radiating less efficiently owing to weaker magnetic 143<br>Barthel, 1983). Most probably such lobes are formed due to<br>relativistic electrons escaping out of the hot spots and<br>therefore radiating less efficiently owing to weaker magnetic<br>field, expansion losses and reduced ener therefore radiating less efficiently owing to weaker magnetic field, expansion losses and reduced energy density (e.g., Scott, 1977). Thus, even though the contribution of the lobes Barthel, 1983). Most probably such lobes are formed due to<br>relativistic electrons escaping out of the hot spots and<br>therefore radiating less efficiently owing to weaker magnetic<br>field, expansion losses and reduced energy d relativistic electrons escaping out of the hot spots and<br>therefore radiating less efficiently owing to weaker magnetic<br>field, expansion losses and reduced energy density (e.g.,<br>Scott, 1977). Thus, even though the contribut (1977), their total energy content is large, indicating a high rate of energy leakage from the hot spots. Based on such considerations we adopt a reasonable upper limit of 0.3 to the value of efficiency with which the power delivered at the hot spot gets radiated away within the hot spots itself. high rate of energy leakage from the hot spots. Based on s<br>considerations we adopt a reasonable upper limit of 0.3<br>the value of efficiency with which the power delivered at<br>hot spot gets radiated away within the hot spots 0.3, Eq.8.10 implies a maximum possible value of  $\rm L_{hs} \sim ~10^{44}$ erg  $s^{-1}$  which can be attained for hot spots powered by  $n$ onrelativistic beams having bulk velocities upto 0.1c. Also, it is seen that for relativistic beams with  $\beta \sim 1$ , L<sub>hs</sub> of upto  $\sim$  3.10 $^{46}$  erg s $^{-1}$  is attainable. In practice this limit would apply to the integrated radio luminosity of double sources, since it is known that in such highly luminous sources little relativistic beams having bulk velocities upto 0.1c. Also, it<br>is seen that for relativistic beams with  $\beta \sim 1$ ,  $L_{hs}$  of upto<br> $\sim 3.10^{46}$  erg s<sup>-1</sup> is attainable. In practice this limit would<br>apply to the integrated r Jenkins and McEllin, 1977; Swarup et al., 1984). In Section 8.2.3 we will discuss the possibility that the luminosity limit derived for relativistic beams may be surpassed because of a possible breakdown of our simplifying assumption of apply to the integrated radio luminosity of double sources,<br>since it is known that in such highly luminous sources little<br>emission arises from regions outside the hot spots (see<br>Jenkins and McEllin, 1977; Swarup et al., 19 luminosities. But this assumption seems justified for hot

144<br>spots of moderate luminosities attainable with non-<br>relativistic beams, which can emit upto  $L_{max} \sim 10^{44}$  erg S<sup>-1</sup><br>for the case  $\beta = 0.1$  and  $\epsilon = \epsilon_{max} = 0.3$ , as discussed relativistic beams, which can emit upto  $\textrm{L}_{\textrm{max}}$   $\sim$   $10^{44}$  erg  $\textrm{s}^{-1}$ 144<br>spots of moderate luminosities attainable with non-<br>relativistic beams, which can emit upto  $L_{max} \sim 10^{44}$  erg s<sup>-1</sup><br>for the case  $\beta = 0.1$  and  $\epsilon = \epsilon_{max} = 0.3$ , as discussed<br>above. If, for the moment, the assumption 144<br>spots of moderate luminosities attainable with non-<br>relativistic beams, which can emit upto  $L_{max} \sim 10^{44}$  erg  $s^{-1}$ <br>for the case  $\beta = 0.1$  and  $\epsilon = \epsilon_{max} = 0.3$ , as discussed<br>above. If, for the moment, the assumption geometry is retained for hot spots of all luminosities, then the following argument shows that the luminosity limits given above for non-relativistic and relativistic beams would hold max<br>
for the case  $\beta = 0.1$  and  $\epsilon = \epsilon_{max} = 0.3$ , as discussed<br>
above. If, for the moment, the assumption of spherical<br>
geometry is retained for hot spots of all luminosities, then<br>
the following argument shows that the lu necessary to produce hot spots of such luminositis; i.e., for  $L_b$  >>  $L_{max}$ for the moment, the assumption of spherical<br>retained for hot spots of all luminosities, then<br>y argument shows that the luminosity limits given<br>n-relativistic and relativistic beams would hold<br>e beam power is much higher t Eq.(8.10) in terms of beam power  $L_b$ : sary to produce hot<br>
b L<sub>max</sub> ( $\epsilon$ ,  $\beta$ )/ $\epsilon$ .<br>

$$
 ... (8.11)

Sary to produce hot spots of such luminositis; i.e., for<br>  $L_{max}$  ( $\epsilon$ ,  $\beta$ )/ $\epsilon$ . To illustrate this, let us rewrite<br>
.10) in terms of beam power  $L_b$ :<br>  $L_{hs}/\epsilon = L_b \approx 5.10^{47} \text{ n}^{-14/3} \text{ g}^{7/3} \text{ g}^{4/3} \text{ erg s}^{-1}$ <br>
.. state with a balance between  $P_{\text{hs}}$  and  $P_{\text{bo}}$  (via Eq.8.7), it is Recalling that this expression characterizes a steady-<br>state with a balance between  $P_{hs}$  and  $P_{bo}$  (via Eq.8.7), it is<br>seen that for given  $\epsilon$  and  $\beta$  there is a critical beam power Eq.(8.10) in terms of beam power L<sub>b</sub>:<br>
L<sub>hs</sub>/ $\varepsilon = L_b \approx 5.10^{47} \eta^{-14/3} g^{7/3} \varepsilon^{4/3} \text{ erg s}^{-1}$  ...(8.11)<br>
Recalling that this expression characterizes a steady-<br>
state with a balance between P<sub>hs</sub> and P<sub>bo</sub> (via Eq.8.7 Eq.8.11 cannot be satisfied for physically meaningful values of  $\eta$  (i.e., for  $\eta \geq 1$ ). For such an excessively powerful beam, therefore, the formation of the hot spot would involve seen that for given  $\epsilon$  and  $\beta$  there is a critical beam power<br>  $L_b^* \sim 5.10^{47} \beta^{7/3} \epsilon^{3/4}$  such that for a more powerful beam<br>
Eq.8.11 cannot be satisfied for physically meaningful values<br>
of  $\eta$  (i.e., for  $\eta \ge$ state with a balance between  $P_{hs}$  and  $P_{bo}$  (via Eq.8./), it is<br>seen that for given  $\epsilon$  and  $\beta$  there is a critical beam power<br> $L_b^* \sim 5.10^{47} \beta^{7/3} \epsilon^{3/4}$  such that for a more powerful beam<br>Eq.8.11 cannot be sati Eq.8.11 cannot be satisfied for physically meaningful values<br>of  $\eta$  (i.e., for  $\eta \geq 1$ ). For such an excessively powerful<br>beam, therefore, the formation of the hot spot would involve<br>an <u>inequilibrium</u> situation. This  $Eq.8.11$  ca<br>
of  $\eta$  (i.e.<br>
beam, ther<br>
an <u>inequil</u><br>
constraint<br>
continuousl<br>
with  $P_{hs}$ <br>
possible wh<br>
factor  $\eta$  ${\rm P}_{\rm bo}$  which for beams having  ${\rm L}_{\rm b}$  >  ${\rm L}_{\rm b}^{\rm g}$  is only r Y<br>
, t<br>
m<br>
1<br>
om<br>
bo<br>  $\leq 1$ <br>
mor beam, therefore, the formation of the hot spot would involve<br>an <u>inequilibrium</u> sitution. This is because the physical<br>constraint  $\eta \geq 1$  would force the hot spot to expand<br>continuously from the (fictitious) equilibrium factor  $\eta^{-1}$  or more implies rapid adiabatic loss, lowering of  $\eta$  (i.e., for  $\eta \geq 1$ ). For such an excessively powerful<br>beam, therefore, the formation of the hot spot would involve<br>an <u>inequilibrium</u> sitution. This is because the physical<br>constraint  $\eta \geq 1$  would force the h beam, therefore, the formation of the hot spot v<br>an <u>inequilibrium</u> sitution. This is because to<br>continuously from the (fictitious) equilibrium<br>with  $P_{hs} \sim P_{bo}$  which for beams having  $L_b$  ><br>possible when  $\eta \leq 1$  (Eq.8 4 below the

(fictitious) equilibrium situation (see Eq.8.8). Thus, for an excessively powerful beam with  $L_{\rm b}$  >  $L_{\rm b}$   $^{\ast}$   $\sim$  5.10<sup>47</sup>  $\beta$   $^{7/3}$ 6.4/3 (fictitious) equilibrium situation (see Eq.8.8). Thus<br>excessively powerful beam with  $L_b > L_b^* \sim 5.10^{47}$   $\beta$ <br>(see above),  $L_{hs}$  would be  $\leq \epsilon L_b$   $\eta$   $\stackrel{4}{\sim}$  8.10<sup>40</sup>  $\beta$  <sup>2</sup><br> $L_b^{1/7}$ . This gives, even for a hi (see above),  $L_{bs}$  would be  $\leq \epsilon L_{b} \eta^{4} \approx 8.10^{40} \beta^{2} \epsilon^{15/7}$ <br>  $L_{b}^{1/7}$ . This gives, even for a highly efficient ( $\epsilon = \epsilon_{max} = 0.3$ ), and excessively powerful beam ( $L_{b}$  say  $10^{48}$  ergs<sup>-1</sup>)  $L_{hs}$ <br>
of  $\sim 4.$ (fictitious) equilibrium situation (see Eq.8.8). Thus, for<br>excessively powerful beam with  $L_b > L_b^* \sim 5.10^{47}$   $\beta^{7/3} \epsilon^{4}$ <br>(see above),  $L_{hs}$  would be  $\leq \epsilon L_b$   $\eta^{4} \approx 8.10^{40}$   $\beta^{2}$   $\epsilon^{15}$ <br> $L_b^{1/7}$ . This give 0.3), and excessively powerful beam ( $\rm L_{\rm b}$  say  $\rm 10 ^{48} erg s^{-1})$   $\rm ~L_{hs}$  $-1$ , of  $\sim$  4.10<sup>44</sup> erg s<sup>-1</sup> if  $\beta$  = 0.1 and  $\textrm{L}_{\textrm{hs}}\sim$  4.10<sup>46</sup> erg s<sup>-1</sup> if  $\beta \sim 1$ . These values are broadly consistent with the limits respectively (see Gopal-Krishna and Saripalli, 1984a.) and excessively powerful beam  $(L_b$  say  $10^{48} \text{erg s}^{-1})$   $L_{hs}$ <br>4.10<sup>44</sup> erg s<sup>-1</sup> if  $\beta = 0.1$  and  $L_{hs} \sim 4.10^{46}$  erg s<sup>-1</sup> if<br>1. These values are broadly consistent with the limits<br>ed above for non-relativistic and r

would produce weaker radio sources. Since outlets of beams associated with lower luminosity sources are neither known nor expected to be systematically smaller (Bridle, 1986), the 146<br>Would produce weaker radio sources. Since outlets of beams<br>associated with lower luminosity sources are neither known<br>nor expected to be systematically smaller (Bridle, 1986), the<br>above mentioned dependence of  $\eta$  wou spots associated with lower luminosity \_sources should be larger in size and thus appear more diffuse. Quantitatively, if one were to define hot spot as a region falling within a circular aperture of a fixed linear radius of, say, a few kpc (e.g., Jenkins and McEllin, 1977), such an aperture would be nor expected to be systematically smaller (Bridle, 1986), the<br>above mentioned dependence of  $\eta$  would predict that the hot<br>spots associated with lower luminosity sources should be<br>larger in size and thus appear more diff sources of decreasing luminosity because of their being systematiclly larger. This could explain the known positive correlation between the radio luminosity of a double source and the fraction of the total extended radio emission that increasingly 'resolving' the hot spots associated with<br>sources of decreasing luminosity because of their being<br>systematiclly larger. This could explain the known positive<br>correlation between the radio luminosity of a doubl correlation was first noted by Jenkins and McEllin (1977) for 3CR sources and more recently supported by Swarup et al. (1984) from VLA observations of a sample of steep spectrum quasars.

#### **8.2.4. The Beam Power and Morphology of Hot Spots**

From the discussion following Eq.8.11,  $L_{hs}$  appears to SCR sources and more recently supported by Swarup et al.<br>
(1984) from VLA observations of a sample of steep spectrum<br>
quasars.<br>
8.2.4. The Beam Power and Morphology of Hot Spots<br>
From the discussion following Eq.8.11,  $L_{$ for 3CR sources and more rec<br>
(1984) from VLA observatio<br>
quasars.<br>
8.2.4. The Beam Power and Mo<br>
From the discussion fo<br>
saturate for beam powers a<br>
could be as high as  $(L_b)_{max}$ <br>
the maximum adoptable value<br>
pointed out  $10^{48}$  erg s  $^{-}$ , corresponding to 8.2.4. The Beam Power and Morphology of Hot Spots<br>From the discussion following Eq.8.11,  $L_{hs}$  appears to<br>saturate for beam powers above a critical value  $L_b$  which<br>could be as high as  $(L_b)_{max} \approx 10^{46}$  erg s<sup>-1</sup>, corres pointed out that higher beam power would induce onset of expansion of the hot spot from the equilibrium configuration, leading to a diminishing of volume emissivity as well as

147<br>
magnetic field strength, which had both been increasing<br>
steadily with beam power until the point of inequilibrium was<br>
reached owing to the constraint  $\gamma \geq 1$ . But, of course, this steadily with beam power until the point of inequilibrium was reached owing to the constraint  $\eta > 1$ . But, of course, this magnetic field strength, which had both been increasing<br>steadily with beam power until the point of inequilibrium was<br>reached owing to the constraint  $\gamma \geq 1$ . But, of course, this<br>constraint could be meaningfully impose 147<br>magnetic field strength, which had both been increasing<br>steadily with beam power until the point of inequilibrium was<br>reached owing to the constraint  $\gamma \geq 1$ . But, of course, this<br>constraint could be meaningfully im valid at least until they reached the point of inequilibrium. If prior to this point, the hot spots were to somehow develop reached owing to the constraint  $\eta \geq 1$ . But, of course, this<br>constraint could be meaningfully imposed only provided our<br>assumption of speterical geometry for the hot spots remained<br>valid at least until they reached the slab along the beam direction,  $P_{hs}$  could be maintained equal to P<sub>bo</sub> (to ensure equilibrium) while the surface of the slab walid at least until they reached the point of inequilibrium.<br>If prior to this point, the hot spots were to somehow develop<br>a slab-like geometry, then by arbitrarily compressing the<br>slab along the beam direction,  $P_{hs}$  co If prior to this point, the hot spots were to somehow develop<br>a slab-like geometry, then by arbitrarily compressing the<br>slab along the beam direction,  $P_{hs}$  could be maintained equal<br>to  $P_{bo}$  (to ensure equilibrium) whi If prior to this point, the hot spots were to somehow develop<br>a slab-like geometry, then by arbitrarily compressing the<br>slab along the beam direction,  $P_{hs}$  could be maintained equal<br>to  $P_{bo}$  (to ensure equilibrium) whi slab along the beam direction,  $P_{hs}$  could be maintained equal<br>to  $P_{bo}$  (to ensure equilibrium) while the surface of the slab<br>in contact with the beam outlet would continue to keep the<br>latter fully covered. Thus, once a arbitrarily high power and, accordingly, its luminosity could increase unconstrained. The crucial transformation from the latter fully covered. Thus, once a slab-like geometry has<br>developed, the volume of the hot spot could arbitrarily<br>reduce to maintain pressure equilibrium with a beam of<br>arbitrarily high power and, accordingly, its luminosi developed, the volume of the hot spot could arbitrarily<br>reduce to maintain pressure equilibrium with a beam of<br>arbitrarily high power and, accordingly, its luminosity could<br>increase unconstrained. The crucial transformatio latter fully covered. Thus, once a slab-like geometry has<br>developed, the volume of the hot spot could arbitrarily<br>reduce to maintain pressure equilibrium with a beam of<br>arbitrarily high power and, accordingly, its luminosi arbitrarily high power and, accordingly, its luminosity could<br>increase unconstrained. The crucial transformation from the<br>spherical to slab-like geometry while the luminosity and the<br>magnetic field of the hot spot are stil reduce to maintain pressure equilibrium with a beam of<br>arbitrarily high power and, accordingly, its luminosity could<br>increase unconstrained. The crucial transformation from the<br>spherical to slab-like geometry while the lum sufficiently high value. The relativistic electrons injected into the hot spot after randomization of their momenta at the increasing beam power (i.e., before the point of<br>inequilibrium is reached) could conceivably occur if the<br>megnetic field in the hot spot has increased to a<br>sufficiently high value. The relativistic electrons injected<br>into lifetimes,  $\mathcal{C}_{syn}$ , shorter than the light travel time,  $\mathcal{C}_{hol}$ , across the beam outlet, leading to the development of a slabshaped hot spot. Such a condition would simply be satisfied which travel time,  $\uparrow$ <br>development of a sl<br>d simply be satisf by electrons having Lorentz factors  $^{9}/r_{\text{bo}}$  B<sub>hs</sub>

where  $B_{\text{hs}}$  is the equipartition magnetic field equal to [3]  $U_{\text{hs}}/\eta_{\text{hs}}$ <sup>0.5</sup>. Eq.8.8 thus leads to: here  $B_{hs}$  is the equipartition m<br>hs/ $x_{hs}$ ]<sup>0.5</sup>. Eq.8.8 thus leads to:<br> $Y_{crit}$  > 2.10<sup>14</sup> n  $L_{hs}^{-4/7}$   $r_{hs}^{5/7}$ 

$$
r_{\text{crit}} > 2.10^{14} \, \text{n} \, \text{L}_{\text{hs}}^{-4/7} \, \text{r}_{\text{hs}}^{5/7} \tag{8.12}
$$

 $B_{hs}$  is the equipartition magnetic field equal to [3<br>
hs<sup>]0.5</sup>. Eq.8.8 thus leads to:<br>  $\gamma_{\text{crit}} > 2.10^{14} \text{ n L}_{hs}^{-4/7} r_{hs}^{5/7}$  ...(8.12)<br>
We substitute for  $r_{hs}$  a typical value of 1 kpc (see<br>
on 8.2.1) and for  $L_{hs$ Section 8.2.1) and for  $\tt L_{\rm hs}$  the limiting luminosity of  $\sim$   $10^{44}$ erg s<sup>-1</sup> attainable for a hot spot powered by a non- $\gamma_{\rm crit} > 2.10^{14} \text{ n L}_{\rm hs}^{-4/7} \text{ r}_{\rm hs}^{5/7}$  ...(8.12)<br>e substitute for  $\text{r}_{\rm hs}$  a typical value of 1 kpc (see<br>n 8.2.1) and for  $\text{L}_{\rm hs}$  the limiting luminosity of  $\sim 10^{44}$ <br>attainable for a hot spot powered b relativistic beam  $(\beta \leq 0.1)$  before its equilibrium breaks down and the expansion of the hotspot begins. Since  $\eta > 1$ , Eq.8.12 thus gives  $\gamma_{crit}$  > 3.10<sup>4</sup>. Thus, the condition for the formation of a slab-shaped hot spot would not be satisfied by all but the most energetic electrons. But they only form an energetically insignificant tail of the steeply falling electron energy distribution which probably peaks at  $\gamma \approx 10^2$ , as inferred for the hot spots in Cygnus A from the Eq.8.12 thus gives  $\gamma$  crit  $> 3.10^4$ . Thus, the condition for<br>Eq.8.12 thus gives  $\gamma$  crit  $> 3.10^4$ . Thus, the condition for<br>the formation of a slab-shaped hot spot would not be<br>satisfied by all but the most energet absorption frequencies of  $\sim$  70 MHz (see Hargrave and Ryle, 1974; Simon, 1977; Saripalli and Gopal-Krishna, 1985). In Falling electron energy distribution which probably peaks at  $\gamma \approx 10^2$ , as inferred for the hot spots in Cygnus A from the estimated magnetic field of  $\sim 3.10^{-4}$  G and synchrotron self-absorption frequencies of  $\sim 70$ beam velocity the point of inequilibrium would only be in met reg<br>

## **8.3. CONCLUSION**

 

sometraint  $\eta > 1$  would no longer be meaningfully imposed for<br>obtaining an upper limit to  $L_{hs}$ , as discussed earlier.<br>8.3. CONCLUSION<br>Within the framework of the beam model we have deduced<br>some basic physical parameter associated with classical double radio sources, following a simple and upper limit to  $L_{hs}$ , as discussed earlier.<br>
8.3. CONCLUSION<br>
Within the framework of the beam model we have deduced<br>
some basic physical parameters of the jets and hotspots<br>
associated with classical double r hot spots radiate under the usual equipartition conditions and that they are roughly spherical in shape. For a sample of 10 bright hotspots and for the jets presumed to be feeding them, we have estimated the densities, bulk velocities, massflow rates and efficiencies of the jets. It is found that the bulk outflow velocity of the relativistic electrons present and that they are roughly spherical in shape. For a sample of<br>10 bright hotspots and for the jets presumed to be feeding<br>them, we have estimated the densities, bulk velocities, mass-<br>flow rates and efficiencies of the jets attains a maximum value of 0.25c (Saripalli and Gopal-Krishna,1985).

A rather natural explanation is found for the known the pess. It is found that the<br>bulk outflow velocity of the relativistic electrons present<br>inside the hotspot, increases with the jet velocity and<br>attains a maximum value of 0.25c (Saripalli and Gopal-Krishna, 1985)<br>A rath bulk outflow velocity of the relativistic electrons present<br>inside the hotspot, increases with the jet velocity and<br>attains a maximum value of 0.25c (Saripalli and Gopal-Krishna, 1985)<br>A rather natural explanation is foun argued that maximum value of  $0.25c$  (Saripalli and Gopal-Krishna, 1985)<br>
A rather natural explanation is found for the known<br>
tendency of more prominent and compact hot spots to be<br>
associated with sources of higher lumi inside the hotspot, in<br>attains a maximum value of<br>A rather natural extendency of more prominos<br>associated with sources<br>argued that the maximum<br>are  $\sim 10^{44}$  and  $\sim 3.10^{46}$ <br>velocities of < 0.1c and<br>could be surpassed  $erg s^{-1}$ aripalli and Gopal-Krishna, 1985)<br>1 is found for the known<br>compact hot spots to be<br>1uminosities. It is also<br>1uminosities of hot spots<br>6, respectively, for beam<br>However, the latter limit<br>0ssible breakdown of the velocities of  $\langle 0.1c \rangle$  and  $\langle \sim c$ . However, the latter limit tendency of more prominent and compact hot spots to be<br>associated with sources of higher luminosties. It is also<br>argued that the maximum expected luminosities of hot spots<br>are  $\sim 10^{44}$  and  $\sim 3.10^{46}$  erg s<sup>-1</sup>, resp associated with sources of higher luminosties. It is also<br>argued that the maximum expected luminosities of hot spots<br>are  $\sim 10^{44}$  and  $\sim 3.10^{46}$  erg s<sup>-1</sup>, respectively, for beam<br>velocities of < 0.1c and  $\sim$  c. How luminosities where their morphology could undergo a qualitative change and become slab-like (Gopal Krishna and Saripalli, 1984a).
